Abstract. This paper presents an analysis of lensing of unresolved background stars. Previous theoretical calculations of the lensing rates and optical depths considered only resolved stars. However, if a faint unresolved star is lensed close enough to a resolved star, the event will be seen by the microlensing experiment and attributed to the brighter star. The blending biases the duration, making the contribution of the unresolved stars very significant for short events. This contribution might be confused with lensing by brown dwarfs. The exact rates of these blended events are extremely sensitive to the limiting magnitude achieved in the microlensing search. Calculations of the optical depth and rates are provided here, and illustrated in the case of the DUO and OGLE experiments. The additional contribution of unresolved stars is very significant. It probably explains the high optical depth and rates observed towards the Galactic Bulge for turn-off stars. The blended unresolved event can be identified using either the color shift or the light curve shape. However, neither of these two methods is appropriate to identify a large number of blended events towards the Bulge. In some case with good photometry and small impact parameter an identification is possible. This is illustrated by the case of the OGLE 5 event, which clearly appears as a case of lensing of an unresolved star. The recent results obtained by the PLANET collaboration indicate that a high resolution and dense sampling of the light curve is possible, and will make possible to correct the blending bias, as demonstrated for OGLE 5. This possibility, is certainly better than a statistical estimation of the lensing rates, which are always prone to some uncertainty. But, at this time, except in the case of the MACHO measurement of the optical depth for the clump giants, the analysis of Microlensing events found in the various microlensing experiments requires the uses of modelisations of the contribution of unresolved stars.

Key words: methods: data analysis – gravitational lensing – Galaxy: stellar content; center

1. Introduction

In previous microlensing models the rates and optical depth per star are usually estimated (Kiraga and Paczyński, 1994 Han and Gould, 1995, Mollerach and Roulet, 1996). Below some limiting magnitude these stars can not be resolved individually and form a dense stellar background on all the surface of the images. We will call these star “background stars”. These background stars can be lensed, this issue has already been investigated in the case of the LMC (Bouquet, 1993), and for the Galaxy (Nemiroff, 1994). The stellar fields of the current Microlensing experiments MACHO (Alcock et al. 1996, Alcock et al. 1993), OGLE (Udalski *et al.* 1994), DUO (Alard 1995a, Alard et al. 1995b), EROS (Aubourg et al. 1993.) are extremely crowded, so that inside the resolution radius of a monitored star, there are plenty of these unresolved background stars. Thus if one of these background stars is lensed, we will see a blended event. The amplification, duration and impact parameter will be biased by the blending. We may now wonder if their contribution to the total number of events observed is significant, compared to those expected from the resolved stars. Blending produces an apparent an apparent reduction of the Einstein Radius (Di Stefano and Esin, 1995). Consequently the observed number of events will be a competition between the decrease of the Einstein radius, and the increasing number of faint stars. Moreover the effective duration of the event will be much shorter than it is for events on resolved stars, and consequently it may produce a tail of short events. These short events could be confused with low mass lens events, and especially those due to brown dwarf, so that a detailed study of these events is particularly important. Another problem is to recognise these blended events. The blending produces a modified light curve which might be distinguished from the unblended light curve. However to make an unambiguous separation a good time sampling is required, and a very accurate photometry is required. In the case of these short events, we expect that it will be difficult to achieve a dense enough sampling.

2. The Bulge luminosity function

The statistics of lensing of unresolved stars is very sensitive to the adopted luminosity function. In previous works (Kiraga and

Paczynski, Roulet and Mollerach, Han and Gould), the number of stars at a given luminosity L is expressed as: $dN = L^{-\alpha}$, with usually $\alpha \simeq 2$. A more realistic luminosity function can be derived from the Holtzman (Holtzman et al. 1993) observations of a field in Baade Window with the HST. This luminosity function can be approximated by three continuous segments with different slopes. The first change in the slope occur at $V \simeq 20$. With the extinction and distance to the Galactic Center adopted by Holtzman et al., it corresponds to $M_V = 4.9$. This agrees well with Terndrup (Terndrup 1989) who finds $M_V = 4.07$ for the Bulge turn-off at $b = -8$. The second change in the slope occur around $V = 21.5$ and the new slope to continues until the limit situated at $V \simeq 22.5$. A comparison with the luminosity function in globular clusters reviewed by Mould (Mould 1996) indicates that the slope of the two luminosity function are similar in this range of magnitude. The Mould diagram allows yields a better determination of the last segment of the luminosity function. This straight segment seems to hold until $M_V = 11$ where there is a possible turnover in the luminosity function. However $M_V = 11$ is about 7 magnitudes fainter than the limiting magnitude of the current microlensing surveys, and such faint unresolved stars do not contribute to the optical depth. The duration of the events on stars blended with a star 7 magnitudes brighter would be so short that it is not observable. Consequently the exact behavior of the luminosity function in this region is not important for our study, and we will cut the luminosity function at $M_V = 11$. Looking now at the bright side of the luminosity function, we find that at magnitudes brighter than the turnoff, the slope is very steep indicating that the number of stars drops rapidly. In this region the Bulge stars are essentially sub giants. The density rises again in the clump giant region, however these stars do not makes more than 5 percent of the stars in the current surveys. Consequently they have not a very significant influence on the total luminosity function. These stars should be treated separately (Alard 1996), and in the present study, we will ignore them. This will put the bright end of the luminosity function at $M_V \simeq 3$ in the Holtzman et al. diagram. The adopted value for the distance to the Galactic center in this study is 8.5 Kpc. The final adopted luminosity function is shown in Fig. 1.

3. Estimation of the lensing rates and optical depth

It is clear that, in an investigation of the lensing of unresolved stars, consistency requires that we calculate the rates and optical depth also with the same luminosity function. This involves some slight changes from previous Kiraga & Paczyński 1994, hereafter referred as KP):

$$d\tau_0(D_s, L) = \frac{dN(D_s, L)}{N_{tot}} \times f(D_s) \quad (1)$$

with:

$$f(D_s) = \frac{4\pi G}{c^2} \int_0^{D_s} \rho_d(D_d) \times \frac{D_d(D_s - D_d)}{D_s} dD_d$$

and $l = L \times \frac{D_s^2}{D_d^2}$. To get the total optical depth we have now to integrate Eq. (1) over the source distances D_s and absolute

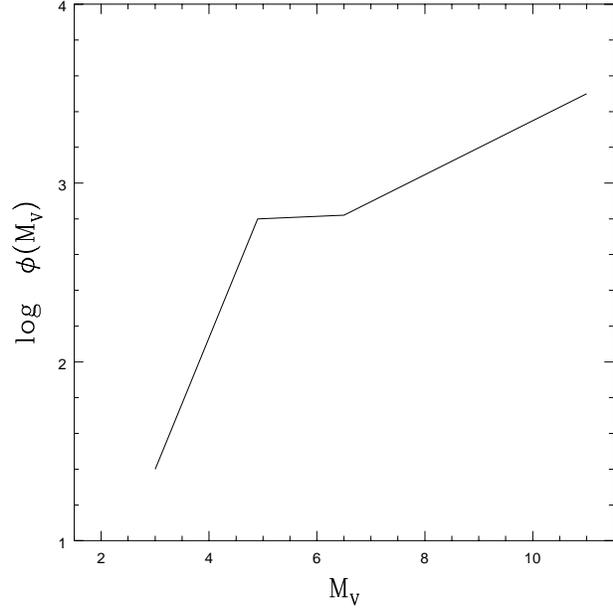

Fig. 1. The adopted Luminosity function for the present study.

luminosities L .

$$\tau_0 = \frac{1}{I_k} \int_{D_s} N_{L0}(D_s) f(D_s) n(D_s) D_s^{2-2\beta} dD_s$$

with:

$$N_{L0}(D_s) = \frac{I_k}{I_d} \times D_s^{2\beta} \int_{L=L_{min}}^{L=L_{max}} l f(L) dL$$

and:

$$I_k = \int_{D_s} n(D_s) D_s^{2-2\beta} dL dD_s$$

Here a factor $D_s^{2\beta}$ is introduced in this expression to allow direct comparison with the standard optical depth formulae (Kiraga and Paczyński 1994):

$$\tau_k = \frac{1}{I_k} \int_{D_s} f(D_s) n(D_s) D_s^{2-2\beta} dD_s$$

We see that the Kiraga and Paczyński expression is simply equivalent to taking $N_{L0}(D_s) = 1$ at all distances. A slight improvement is to take $N_{L0}(D_s) = 0$ beyond a given distance (Roulet & Mollerach, 1995). The plot in Fig. 2 allows a direct comparison between $N_{L0}(D_s)$, and the approximation $N_{L0}(D_s) = 1$. Fig. 2 illustrates the calculations both for DUO and for the OGLE experiment, which is about one magnitude deeper. Let's see now the changes in the total optical depth introduced by the $N_{L0}(D_s)$ function. The optical depths are computed using the COBE bar model for the Bulge (Dwek et al., 1995), and the Bahcall model for the Disk (Bahcall and Soneira, 1984) The ratio of the modified optical depth to the standard one is shown in Table 1. The change is already important for OGLE, and is more significant again for DUO. It is easy to understand that the lower optical depth of the new formulae

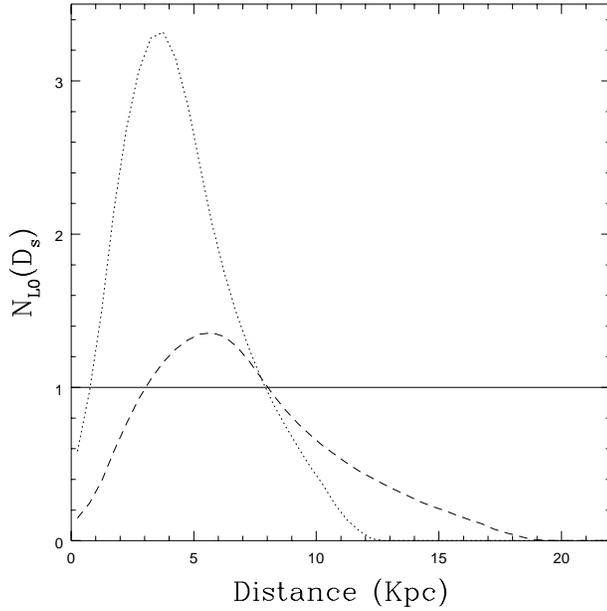

Fig. 2. Plot of the $N_{L0}(D_s)$ function as a function of distance. For the DUO experiment a limiting magnitude of $M_V = 3.5$ at the distance of the Galactic Center was adopted, OGLE is assumed to be one magnitude deeper. The dotted line is for DUO, and the dashed line for OGLE.

Table 1. Optical depth ratio for DUO and OGLE

| Optical depth ratio | Bulge lenses | Disk lenses | Total |
|---------------------|--------------|-------------|-------|
| OGLE | 0.85 | 0.89 | 0.86 |
| DUO | 0.75 | 0.8 | 0.77 |

is essentially due to the fact that due to the limiting magnitude, the experiments are more sensitive to sources in the near end of the bar, for which the density of lenses on the line of sight is smaller.

3.1. Event rates

The formulae given for the lensing rates by Kiraga & Paczyński is:

$$\Gamma_k = \frac{1}{I_k} \int_{D_s} f_\gamma(D_s) n(D_s) D_s^{2-2\beta} dD_s$$

Where:

$$f_\gamma(D_s) = \frac{4 G^{1/2}}{cM^{1/2}} \int_0^{D_s} \int_{V_i} \rho_d(D_d) V(D_s, D_d) \times \left[\frac{D_d(D_s - D_d)}{D_s} \right]^{1/2} dD_d dV_i$$

$V(D_s, D_d)$ is the relative velocity between lens and source, and the V_i are the four components of this velocity.

Now, it is straightforward to introduce the $N_{L0}(D_s)$ function in this expression, exactly as it was done for the optical depth.

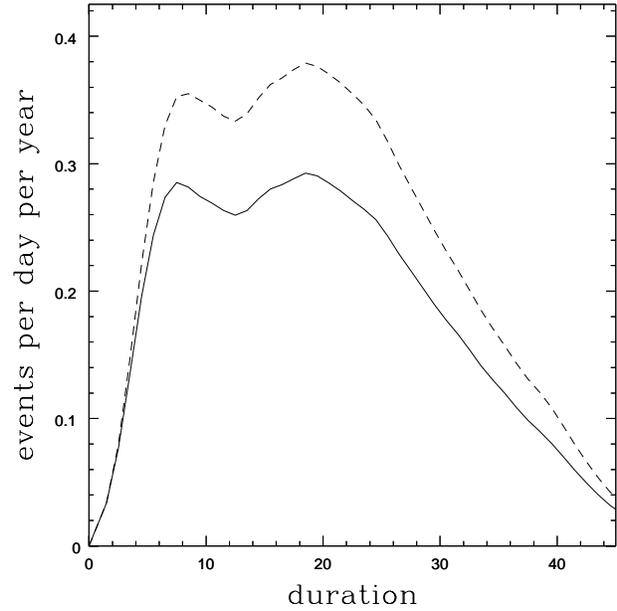

Fig. 3. Comparison of the total rates of events for Bulge sources using KP formulae (dashed line), and the formulae described in this text (solid line). The total rate is estimated for the 1994 season of the DUO experiment using the DUO efficiencies (Alard and Guibert 1996). The two bumps are due to the particular shape of the DUO efficiencies.

This leads to:

$$\Gamma_0 = \frac{1}{I_k} \int_{D_s} N_{L0}(D_s) f_\gamma(D_s) n(D_s) D_s^{2-2\beta} dD_s$$

The result of the calculation of the Γ_0 and Γ_k rates is shown in Fig. 3 for DUO, and in Fig. 4 for OGLE. For all the figures the velocity dispersion given by Han & Gould (1995) was adopted. The mass function is a Salpeter mass function with a lower cut off at $0.08M_\odot$ and an upper cut off at $1M_\odot$.

4. Modelling the lensing of blended unresolved stars

4.1. Basic principles

The Einstein radius is the distance to the lens for which the amplification of a microlensing event is a factor of 1.34. In the case of an unresolved background star of luminosity l_0 , blended with a resolved star of magnitude L_0 , the background star amplification required to make a total amplification in the combined image of 1.34 is:

$$A_b = 0.34 \times f_b + 1.34$$

f_b being the blending factor:

$$f_b = L_0/l_0$$

This gives the following expression for the blended Einstein radius:

$$R_b(f_b) = R_e \times re_b(f_b)$$

with:

$$re_b(f_b) = \left[2(-1 + A_b/\sqrt{A_b^2 - 1.0}) \right]^{1/2}$$

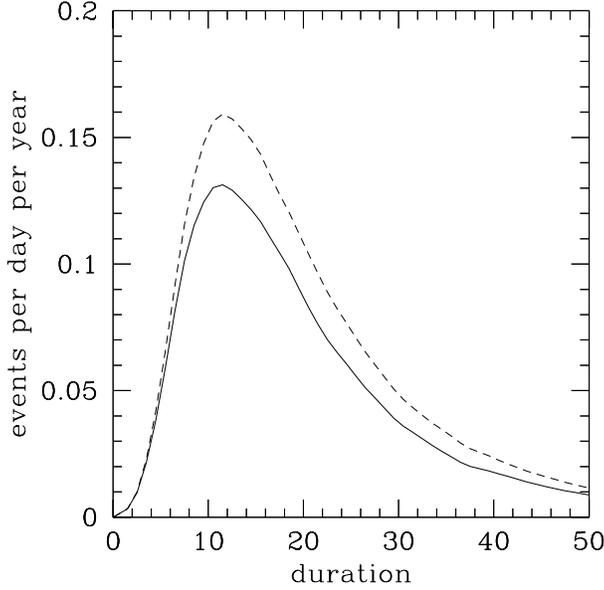

Fig. 4. Comparison of the total rates of events for Bulge sources using KP formulae (dashed line), and the formulae obtained here (solid line). The total rate is estimated for 10^6 stars in Baade window using the OGLE efficiency (Udalsky et al. 1994)

4.2. Optical depth due to the unresolved stars

Let us consider unresolved background stars with absolute luminosity L at a distance D_s , whose number is $dN(D_s, L)$, and assume that they are blended with stars of apparent luminosity l_b . The optical depth per resolved star associated with these stars can be calculated using Eq. (2) by replacing the Einstein radius by the blended Einstein radius.

$$d\tau(D_s, L) = \frac{dN(D_s, L)}{N_{tot}} \times r_b(l_b, l) \times f(D_s) \times R$$

The expression for $d\tau$ contains the factor R , which takes into account that only those unresolved objects which are lensed close to a resolved star will be seen. The Value of R will be close to the ratio of the area of the seeing disk, to the mean space occupied by a star on the image. with: $r_b(l_b, l) = [r_{e_b}(f_b)]^2$, and $f_b = l_b/l$.

We have now to take into account that the luminosity l_b of the resolved is described by a luminosity function. It was shown by Zhao (Zhao 1995) using the OGLE data that the number of resolved stars in Baade's window can be well described by a power law, with an exponent close to -2 . To be precise we have a fraction of stars at luminosity l_b :

$$dF(l_b) = \beta_2 l_b^{-\alpha_2} l_0^{\beta_2} dl_b \quad (2)$$

with: $\alpha_2 \simeq 2$ and $\beta_2 = \alpha_2 - 1$ consequently,

$$d\tau(D_s, L, l_b) = d\tau(D_s, L) \times dF(l_b)$$

To get the total optical depth associated with the unresolved stars, we have now to integrate over the luminosity range of

these stars, from the absolute luminosity (L_{min}) to the faint end of their luminosity function (L_{end}).

In addition, we have also to integrate over all the possible distances for the sources, and all apparent luminosities for the blends.

This leads to:

$$\tau = \int_{L=L_{end}}^{L=L_{min}} \int_{D_s} \int_{l_b=l_0}^{l_b=l_{sat}} \frac{dN(D_s, L)}{N_{tot}} \times dF(l_b) R r_b(l_b, l) f(D_s) dD_s dL dl_b$$

If now we uses Eqs. (1–3), we can express τ as:

$$\tau = \frac{R}{I_d} \times \beta_2 l_0^{\beta_2} \int_{D_s} \int_{L=L_{end}}^{L=L_{min}} \int_{l_b=l_0}^{l_b=l_{sat}} l_b^{-\alpha_2} r_b(l_b, l) \times l f(L) f(D_s) n(D_s) D_s^2 dL dl_b dD_s$$

This expression can be integrated over the variables L and l_b , consequently:

$$\tau = \frac{1}{I_k} \int_{D_s} N_L(D_s) f(D_s) n(D_s) D_s^{2-2\beta} dD_s$$

with:

$$N_L(D_s) = \frac{I_k}{I_d} R \beta_2 l_0^{\beta_2} D_s^{2\beta} \int_{L=L_{end}}^{L=L_{min}} \int_{l_b=l_0}^{l_b=l_{sat}} l_b^{-\alpha_2} r_b(l_b, l) \times l f(L) dL dl_b$$

Note that the dependence in distance is hidden in the variable $l = L \times D_0^2/D_s^2$, and also in the boundary L_{min} .

Fig. 5 illustrates the new $N_L(D_s)$ function for the unresolved stars in the case of the DUO and OGLE experiments. Note that these functions reach their maxima at larger distances than the previous $N_{L0}(D_s)$ functions: this means that a large contribution will come from unresolved sources on the far side of the bar. It is now possible to quantify the contribution of the unresolved sources to the total optical depth. In Table 2 the ratio of the optical depth of unresolved sources to the the optical depth of resolved sources is indicated for DUO and OGLE. The calculation of this ratio require an estimation of the R constant. A crude estimate of R is the ratio of the surface covered by the resolution radius to the mean area occupied by a star. For the DUO experiment the resolution radius is close to 3 pixels, and the mean area occupied by a star is about 60 pixels (Alard and Guibert 1996). This gives $R \simeq 0.5$. For OGLE the resolution radius is probably close to the seeing value (this is due to smaller pixels). Consequently with a mean seeing of $1.25''$ in Las Campanas, and a pixel of $0.44''$ we can estimate the resolution radius as 2.7 pixels. The OGLE experiment follows 1.3×10^6 stars on 14 images of 2048×2048 pixels each. This gives again $R \simeq 0.5$.

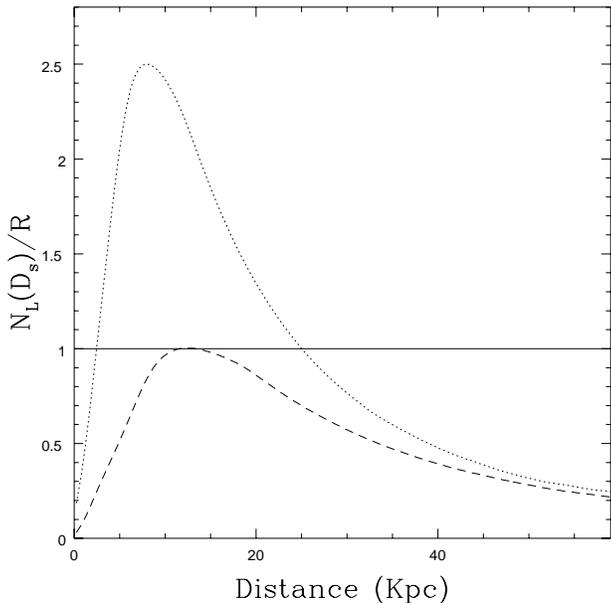

Fig. 5. Plot of the $N_L(D_s)/R$ function as a function of distance for unresolved sources. The limiting magnitude defined for Fig. 1 were kept for this illustration. The dotted line is for DUO, and the dashed line for OGLE.

Table 2. Ratio of the optical depth of unresolved sources to the optical depth of resolved sources. A value of $R = 0.5$ is adopted for the calculations (see text for discussions).

| τ/τ_0 | Bulge lenses | Disk lenses | Total |
|---------------|--------------|-------------|-------|
| OGLE | 0.58 | 0.55 | 0.57 |
| DUO | 1.93 | 1.81 | 1.89 |

4.3. The rates of microlensing events from unresolved stars

The rates of unresolved events per resolved star can be calculated in the same way as for the optical depth. We have:

$$\Gamma = \frac{1}{I_k} \int_{D_s} N_{L\gamma}(D_s) f_\gamma(D_s) n(D_s) D_s^{2-2\beta} dD_s \quad (3)$$

with:

$$N_{L\gamma}(D_s) = \frac{I_k}{I_d} R \beta_2 l_0^{\beta_2} D_s^{2\beta} \int_{L=L_{end}}^{L=L_{min}} \int_{l_b=l_0}^{l_b=l_{sat}} l_b^{-\alpha_2} re_b(l_b, l) \times lf(L) dL dl_b$$

It is clear that a change of the Einstein radius by the factor $re_b(l_b, l)$ changes also the duration by the same factor. Consequently in the differential rates calculation, each duration $t_E = r_E/V$ will have to be scaled by the factor $re_b(l_b, l)$. However, we see in Eq. 4 that for a given Einstein radius there is a distribution of scaling factors $re_b(l_b, l)$ hidden in the double integral $N_{L\gamma}(D_s)$. This distribution can be calculated for each distance D_s , and for the realisation of the calculations, the scaling factor of the Einstein radius will be chosen by a Monte-Carlo method using this distribution. Some examples of

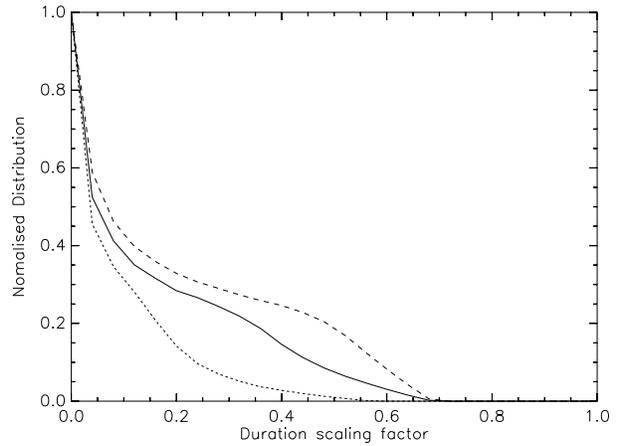

Fig. 6. Examples of duration scaling factor distribution functions, for different distances. The solid line is for a distance of 8 Kpc, the long dashed line is for 15 Kpc, and the short dashed line is for 6 Kpc.

such distributions for different distances are shown in Fig. 6, in the case of the DUO experiment.

The result of the calculation of the Γ_0 and Γ_k rates is shown in Fig. 7 for DUO, and in Fig. 8 for OGLE. It is evident that the DUO experiment is dominated by unresolved stars. This result is in very good agreement with the data (Alard and Guibert 1996). Even for OGLE which has the deepest photometry, the bias is still very significant. It is rather straightforward to relate these events to the excess in the rates and optical depth observed towards the Bulge. This excess was not explained before, even using a bar in the Galactic model. We find here a natural explanation.

5. Can we identify the blending events using the light curves?

The light curve of a blended event is affected by the additional light coming from the companion, so that the light curve is modified. This blended light curve has more extended wings than an unblended event, so that it might be possible to differentiate it from the unblended one using a chi-square test.

Another important issue is the possibility that the amplified star and its companion may have different colors. For instance if the companion is bluer than the amplified star, we expect more blending in the blue, and thus a larger reduction of the amplitude in this color than in the red.

5.1. Color variations

Let us now investigate the problem of color variation during the event in more detail. In the current microlensing experiments the sources are concentrated in the range $18 < V < 20$. An examination of Terndrup (Terndrup, 1988) color magnitude diagram in Baade's window indicates that the mean $V - I$ color is about 1.3 to 1.4. For fainter stars, where we expect to find the unresolved sources, the Holtzman et al. color magnitude diagram shows that the color changes again very slightly. The mean color is close to 1.4 at $V = 22$. We see that in the appar-

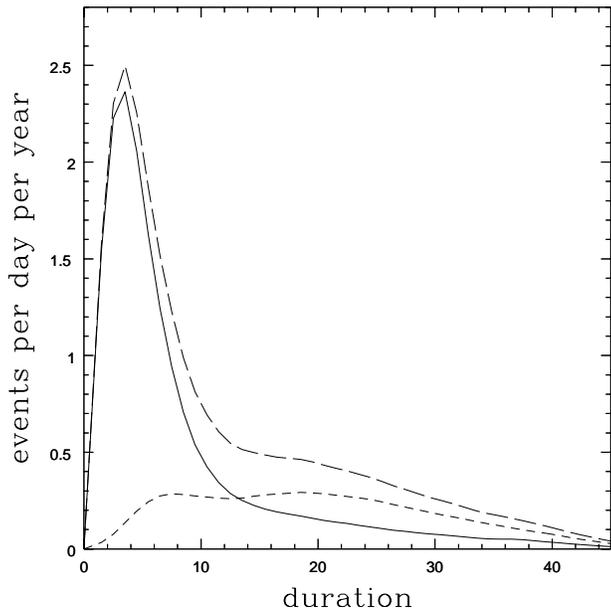

Fig. 7. Comparison of the contribution to Bulge microlensing event rates for resolved stars (short dashed line), and unresolved stars (solid line). The total rate is represented by a long dashed line. The rates are estimated for the 1994 season of the DUO experiment using the DUO efficiencies (Alard and Guibert 1996). Note the dominant contribution of the unresolved stars.

ent magnitude range of interest we expect a differential color variation of about 0.1 magnitude at most between the unresolved source and the blending companion. We have to reach $V = 23$ to reach more significant color variation (about 0.2 magnitudes). Unfortunately the photographic technique does not perform very well in the red band, thus an accurate investigation of the color changes during the event is not possible. It means that the DUO survey will not be able to detect the slight expected color changes. The OGLE survey has a good coverage only in the I band, the sampling in V is very sparse, and does not allow color analysis during the event. In the MACHO case, photometric data are available in two large bandpasses, which is transformed to a $V - R$ color index. The analysis of the LMC events by the MACHO team shows that they can identify color variations due to blending for some of the events. However there is a small residual noise on the color variations of all the events of about 0.02 to 0.03 magnitudes, associated with the photometric errors. At a 3σ confidence level a color variation of about 0.075 magnitude is required in the MACHO case to firmly establish the chromaticity of the event. Converted to $V - I$ it requires a color changes of about 0.15 magnitudes at least to recognise a blended event with a good confidence level.

We consider now how many of the Bulge microlensing events which involves unresolved sources could be identified with such accuracy.

Let us make the following simple model: We assume that the difference of color can be described by a gaussian distribution,

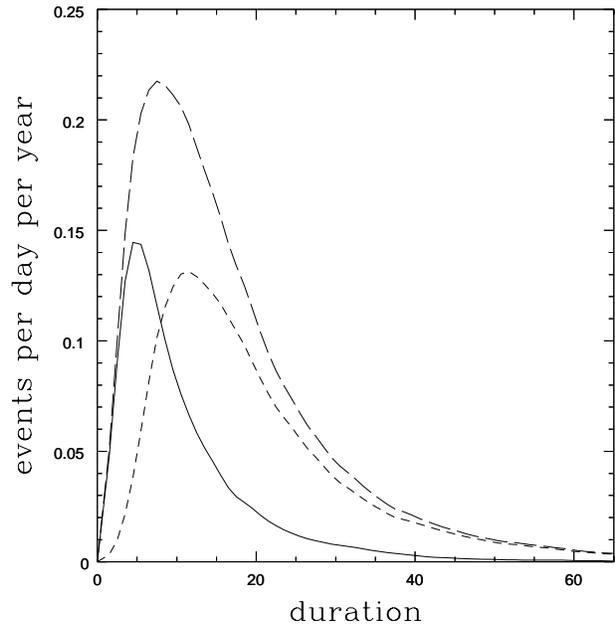

Fig. 8. Comparison of the contribution to Bulge microlensing event rates for resolved stars (short dashed line), and unresolved stars (solid line). The total rate is represented by a long dashed line. The rates are estimated for 10^6 stars in Baade window using the OGLE efficiency (Udalsky et al. 1994).

shifted by a systematic value. Thus the number density $n(C)$ of stars with color a difference in color C will be expressed as:

$$n(C) = \exp\left(\frac{(C - \Delta_c)^2}{-2\sigma_c^2}\right) \quad (4)$$

The Holtzman et al. color magnitude diagram indicates that we can assume $\sigma_c \simeq 0.07$. In the range $V = 20$ to $V = 22$, a conservative value for the shift is $\Delta_c \simeq 0.15$. The color shift is then given by:

$$\Delta_C = 2.5 \log(A_i/A_v)$$

i and v stand where the subscripts for the two photometric colors. with:

$$A_i = \frac{1 + af_b}{1 + f_b}$$

and:

$$A_v = \frac{1 + af_b c}{1 + f_b c}$$

a and c are defined by the following expressions:

$$a = \frac{u^2 + 2}{u \times \sqrt{u^2 + 4}} \quad c = 10^{C/2.5}.$$

The number of events with color blending signature identified will be simply the number of events with a color shift $\Delta_C > 0.15$. It can be easily calculated if we assume that the unblended impact parameter u has a uniform distribution. In this case it is sufficient to integrate the number of events with $\Delta_C > 0.15$ over the u distribution with a given color difference C . The calculation is completed by summing over the color difference

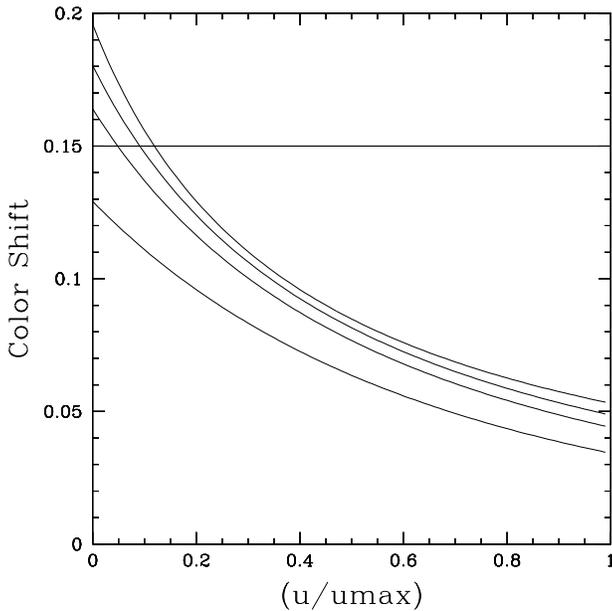

Fig. 9. The distribution of the color shift for blending parameters of 2,5,10,50, and a color difference of 0.2. The curve with $f_b = 50$ is upper, and the values 10,5,2, are below in a decreasing order.

distribution defined in Eq. (5). The maximum value of the impact parameter is set by the blending factor f_b using the formulae:

$$u_{max} = \left[2(-1 + A_b/\sqrt{A_b^2 - 1.0}) \right]^{1/2} \quad (5)$$

with:

$$A_b = 0.34 \times f_b + 1.34$$

The calculation of the percentage of events with color shifts is performed for several values of the blending factor f_b . An illustration of these calculations is given in Fig. 9, where the color shift is expressed as a function of the impact parameter for a few f_b values, and a color difference of 0.2 magnitude. Looking at this diagram we can already guess that the number of events with detectable color shifts will be small. The final fraction of events with color shifts identified is given in Table 3. They are extremely small. The maximum color shift is about 0.15 mag, even for high values of the blending factor. The values for a shift of 0.3 magnitudes are also given, to illustrate the case of the very faint unresolved stars. However these stars will be extremely blended, and consequently will give events will very short duration which will be almost all removed by the low efficiency of the experiments in this range. Consequently the color shift method will give poor results in the case of the Galactic Bulge. In the case of the Magellanic Clouds, the color changes rapidly when the magnitude is close to the limit of the microlensing experiments, which explains why so many events with color shifts are found by MACHO (Alcock, et al., 1996) towards the LMC.

Table 3. The fraction of events with detectable color shifts.

| Blending factor | 2 | 5 | 10 | 50 |
|---------------------------|--------|--------|--------|--------|
| shift _c = 0.15 | 0.0025 | 0.0219 | 0.0364 | 0.0485 |
| shift _c = 0.3 | 0.1677 | 0.3079 | 0.3559 | 0.3906 |

5.2. The shape of the light curves

In this Sect. I will investigate another possibility to identify a blended microlensing event based on the shape of the light curve. The blending of light modifies the shape of the light curve, and consequently we may use a statistical test to see if a light curve differs significantly from an unblended one. We have to realise that the difference due to blending is rather small, and will be difficult to identify a blended light curve at a significant level of confidence. It is possible to adress this problem in more general terms using Monte-Carlo simulation of microlensing events. Assuming a noise distribution, it is easy to simulate microlensing events with different blending factors. These blended events can be analysed by fitting an unblended curve to the simulated data set. We expect a systematic difference in the chi-square of the fit due to the different shape of the blended light curve, especially in the wings. However the problem is to know how significant this difference is compared to the normal variations for unblended events due to noise. This problem can be easily addressed if we are able to build the chi-square distribution for a series of blended light curves. Such chi-square distributions are illustrated in Fig. 10, the line shows the limit within which 95 percent of the chi-square distribution for unblended events is contained. Beyond this limit there is a 95 percent confidence level that the chi-square indicates a light curve which is systematically different from the unblended model. It is now sufficient to sum the fraction of the blended distribution beyond this limit to get the fraction of blended events R_b which can be identified with a good confidence level. The ability to recognise a blended event will of course depend on the amplitude of the event, for a given blending factor f_b and a given duration t_0 . The amplitude is related to the impact parameter u . Consequently to get the expected fraction R_b , at f_b and t_0 it is sufficient to sum on the impact parameter u , in the range 0 to u_{max} (u_{max} is defined in Eq. 6). The result of the corresponding calculation is illustrated in Fig. 11, as a function of the blending factor, for various durations. The blended events are well identified only for small impact parameters. Beyond $u_{max}/10$, the efficiency drops significantly, which makes the total efficiency quite low. These tabulated expressions of R_b as a function of f_b and t_0 are now introduced directly in the calculation of the unresolved event rates. Then new rates corrected for the number of blended events which could be recognised are computed. Fig. 12 shows a comparison between this rate and the uncorrected rate in a case resembling the OGLE experiment. Typical errors distributions are extrapolated from the DUO experiment (Alard and Guibert 1996), and are divided by a scaling factor of 2 to take into account the better quality of the OGLE photometry. The resulting errors distribution has a r.m.s. about 0.07 magnitude

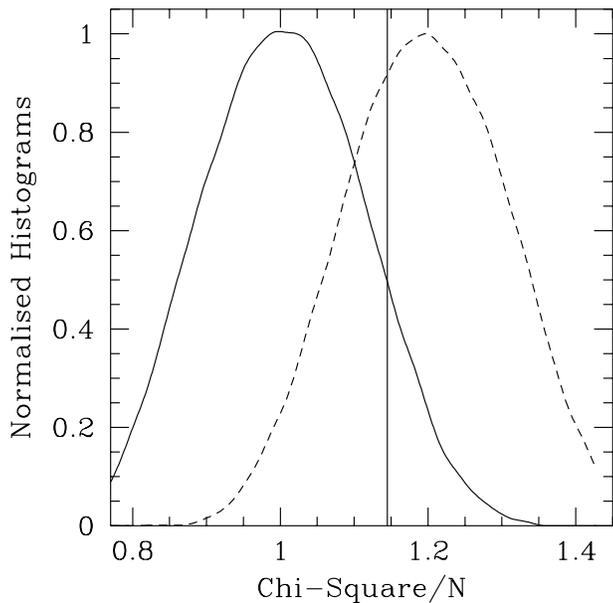

Fig. 10. An example of simulated Chi-square distributions for unblended events (full line), and for blended events (dashed line). The vertical line indicates the 95 percent limit for the unblended distribution (see text for explanations). For this example the events are simulated with a duration of 40 days, and an impact parameter of 0.05. The blending factor has a value of 4.

for most of the points, and reaches 0.1 or slightly more in 10 percent of the cases; it seems to be an acceptable description of the OGLE photometry on stars close to the limiting magnitude, which represent most of the sample. We see that the difference is small, and considering that OGLE has the best photometric accuracy, it is certainly worse again for the others experiments.

As for the color test, the conclusion is, that given the mean quality of the photometry available in the microlensing experiments, only a slight percentage of blended events can be recognised on the basis of the light curve shape. Only the events with good photometry and small impact parameter can be identified as blended. However for some of the monitored stars the OGLE experiment is able to perform photometry much better than for the majority of the stars. This gives an interesting opportunity to look for a blending signature in the light curves.

6. OGLE 5: an example of lensing of an unresolved star

The photometry achieved on the OGLE 5 event is of excellent quality, the errors bars are as good as a few percent on many points. However this event is not well fitted with the standard unblended model (see Fig. 13). The discrepancy is especially large in the wings of the event, so that it is natural to try to fit this event with blending. Fig. 14 shows the dramatic improvement of the chi-square when a blended light curve is fitted. The best fit is obtained for a blending factor of 2.45 (Fig. 15.). This makes the lensed source 1.34 magnitude fainter, and places it below the OGLE detection limit. Consequently it is very likely that OGLE 5 is an example of lensing on an unresolved star. The best Chi-

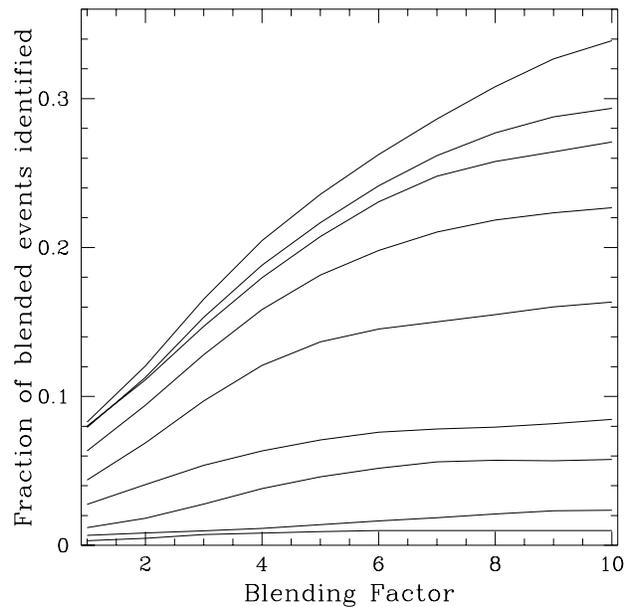

Fig. 11. The fraction of blended events identified as a function of the blending factor for different event durations. The durations are respectively 100,63,25,15,10,6,4,2.5 days (from top to bottom).

Square per degree of freedom is different from unity, but we have to recall that an event on an unresolved star is seen only through blending on a resolved star. For the photometry, the position of the resolved star is used, but it might be significantly different from the position of the true magnified star. The achieved errors in a PSF fitting routine are rather sensitive to the quality of the positioning, thus we expect somewhat larger errors in the case of an unresolved event. The small discrepancy in the Chi-Square per degree of freedom is thus consistent with the scenario of an unresolved event.

7. Discussion

In this paper I show that the rates of microlensing events and optical depth to microlensing due to the unresolved stars can be modelled. However I emphasize that the exact rates and optical depth are closely related to the number of unresolved stars which will contribute per observed star. This number is well constrained in crowded fields, essentially because the surface occupied by a star on the image is set by the crowding limit. On the other hand, this crowding limit is closely related to the resolution radius, thus the surface occupied by a star image is only a function of this resolution radius. A value of 0.5 was found for the ratio R of the surface covered by the resolution radius to the mean surface occupied by a star, both for DUO and OGLE. This simply means that probably there is a linear relation between the resolution radius and the mean radius per star.

However in the crowded fields, if a new star appear at more than a resolution radius, it does not mean necessarily that it will be resolved. The density of stars is so high that it might well be confused with another one. This issue should be clarified later

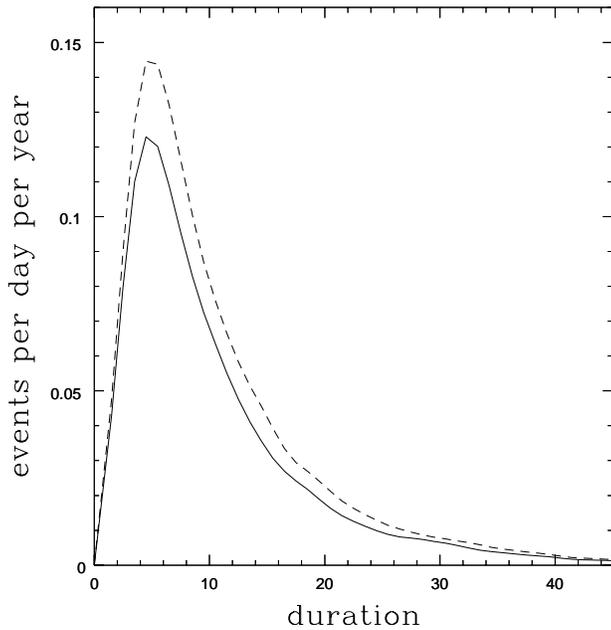

Fig. 12. The event rate statistically corrected for the fraction of blended stars which might be identified on the basis of their light curve shape. The corrected rate is represented by a full line, and the initial rate by a dashed line.

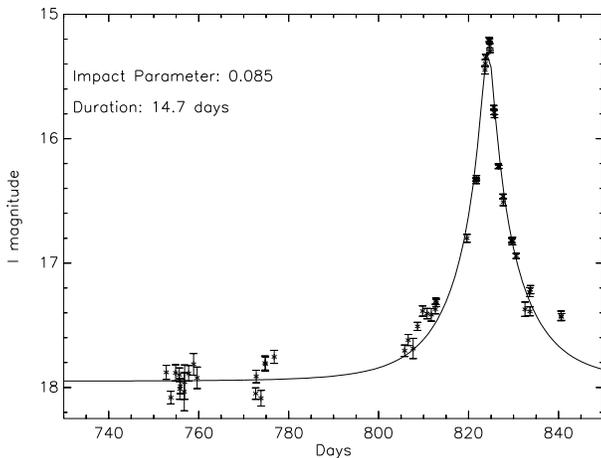

Fig. 13. The fit of an unblended light curve to the data, note the large discrepancy in the wings.

using Monte-Carlo simulation of crowded fields. This effect will probably lead to a slight increase of R . Another problem is that if the amplified star is situated at some distance from the resolved star the photometry which assumes fixed positions (except for DUO) is certainly affected. This possibility was already discussed in the case of OGLE 5 and will cause a slight drop in the efficiency, which will increase as the unresolved star will be more distant from the resolved one. This issue could also be clarified later using Monte-Carlo simulation. But globally, this effect will more or less cancel out with the confusion effect exposed just before. Thus, the value $R = 0.5$ seems an acceptable approximation.

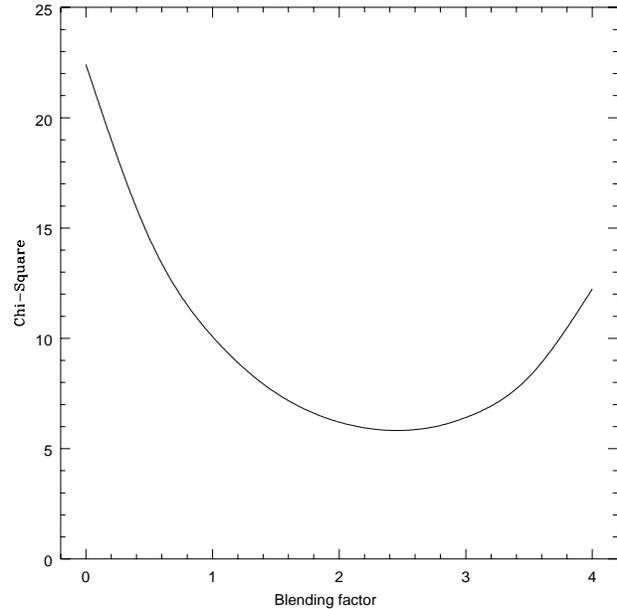

Fig. 14. The Chi-Square per degree of freedom obtained for a fit to the data for OGLE 5 with different blending factors.

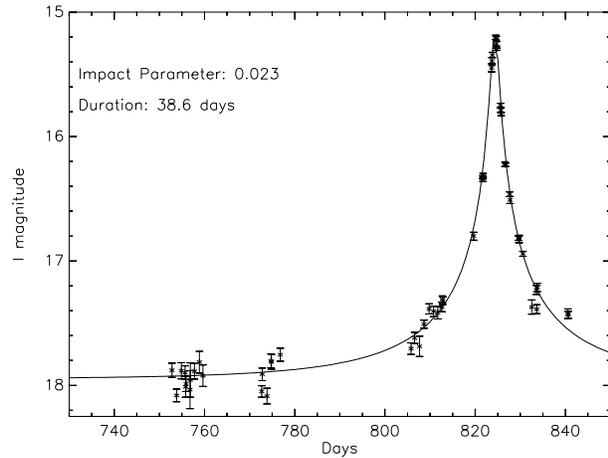

Fig. 15. The best fit with blending, note the large change in the estimated duration in comparison with the unblended fit.

8. Conclusion

The modeling of the unresolved star microlensing rates demonstrates that they induce an important bias for the short events. I show that given the current photometric errors, most of these events are hard to distinguish from the unblended events. Thus this is an important and annoying bias. If this bias is not taken into account, it will certainly influence the shape of the lens mass function estimated from the data. For instance, if a Salpeter mass function is used, we expect that the lower cut-off will be shifted towards the brown dwarfs. This idea is illustrated in Fig. 16 where the total OGLE rates (resolved+unresolved) are compared to the rates for Salpeter mass functions with different lower cut-offs (I recall that initially I used a Salpeter mass function with a lower cut-off of $0.08M_{\odot}$ to compute the OGLE

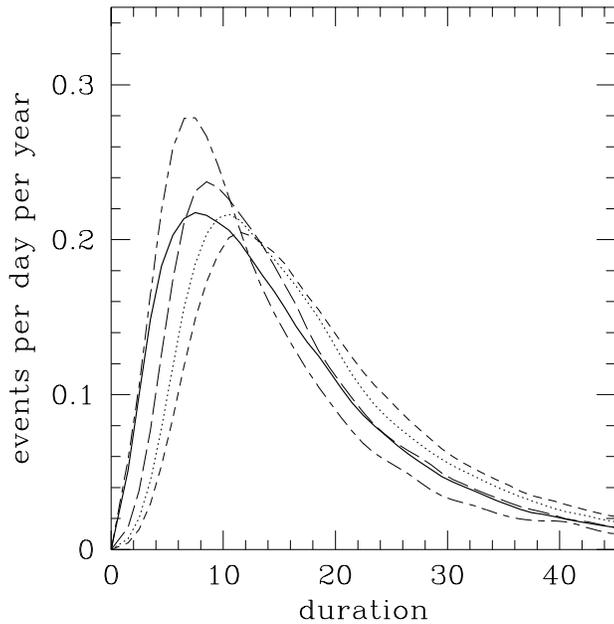

Fig. 16. Comparison of the total microlensing rates (unresolved+resolved stars) with the rates for resolved stars for different cut-offs in the mass function in case of the OGLE experiment. The cut-offs are: $0.02 M_{\odot}$ (long and short dashed line), $0.04 M_{\odot}$ (long dashed line), $0.06 M_{\odot}$ (dotted line), and $0.08 M_{\odot}$ (short dashed line). The scaling factors are respectively: 1.09, 1.24, 1.18, 1.28 (see text for explanations).

and DUO rates). A better agreement with the total rates is found if the different trial models are slightly scaled. I calculated this scaling factor, so that the trial models give the same total rates in the range 0 to 80 days as the total rate (see Fig. 16.). The case of the DUO experiment will be treated in another paper (Alard and Guibert 1996). While the unresolved star bias has to be taken into account, as demonstrated in the previous section, the modelling includes some uncertainties. However for the data set already assembled by the microlensing experiments, it is certainly an acceptable solution to the unresolved star bias. For the future, a very interesting possibility is offered by the PLANET (Sackett, 1995) collaboration, who will provide a dense and accurate sampling of the events. It will allow a much better control of the bias caused by the unresolved, using both the color shift and importantly the shape of the light curve, as demonstrated in the case of OGLE 5.

To conclude, I emphasize that the contribution of the unresolved stars drops if the magnitude limit is increased. This is well illustrated by the comparison OGLE vs. DUO. Consequently a first solution is to try to reach stars as faint as possible to minimise the bias. It is certainly a possible orientation for the OGLE II experiment, which will achieve improved resolution with a new telescope. On the other hand for the MACHO and EROS II experiments, which use bigger pixels, and cover larger fields, an interesting solution is certainly to monitor the bright clump giants. These stars are much brighter (about 3 magnitudes) than most of the bulge stars, and their density per image

is also much lower. Thus, the unresolved stars per giant will be low and they will be so blended that the effective Einstein radius will be very small. The unresolved star bias will be very small on clump giants. Some other advantages of the clump giants include the better photometry, and also the possibility to have a sample with very high completeness (Gould 1995). Some investigations of the clump giants optical depth have already been performed by the MACHO group (Bennet et al., 1995). Their estimation seems to indicate a high optical depth, if this results is confirmed by the analysis of a larger number of events, this would be a very interesting clue.

Acknowledgements. It is a great pleasure to thank B. Paczyński, Gerry Gilmore, Olivier Bienaymé and Gary Mamon for interesting discussions.
